FINITE SIZED ATOMISTIC SIMULATIONS OF SCREW DISLOCATIONS

VIJAY B. SHENOY AND ROB PHILLIPS

Division of Engineering, Brown University, Providence, RI 02912

Abstract

The interaction of screw dislocations with an applied stress is studied using atomistic simulations in conjunction with a continuum treatment of the role played by the far field boundary condition. A finite cell of atoms is used to consider the response of dislocations to an applied stress and this introduces an additional force on the dislocation due to the presence of the boundary. Continuum mechanics is used to calculate the boundary force which is subsequently accounted for in the equilibrium condition for the dislocation. Using this formulation, the lattice resistance curve and the associated Peierls stress are calculated for screw dislocations in several close packed metals. As a concrete example of the boundary force method, we compute the bow out of a pinned screw dislocation; the line-tension of the dislocation is calculated from the results of the atomistic simulations using a variational principle that explicitly accounts for the boundary force.

1 Introduction

Atomistic simulations with carefully chosen potentials have been shown to account for the structure and energetics of a range of extended defects (Vitek 1992). Despite these successes, one of the main drawbacks of atomistic simulations is that they are limited to small simulation cells, necessitating an approximate treatment of boundary conditions. A popular method used in the simulation of dislocations is to use a *finite sized* simulation cell and to adopt the continuum linear elastic solution for the defect of interest as the initial trial solution for the atomistic energy minimisation with the additional constraint that the atoms on the boundary of the cell be fixed at the positions dictated by the elastic solution. The rationale behind this approach is that at large distances from the core of the defect, continuum linear elasticity provides an accurate description of the displacement, strain and stress fields. This method has been applied with much success to the determination of the static core structure of dislocations (Vitek 1992). Upon application of an applied stress, the defect of interest will adopt a new equilibrium configuration. In particular,

the dislocation core moves relative to the axis of symmetry of the simulation cell. This motion is influenced by the boundary, i.e., the defect encounters *an additional force* that depends on its position relative to the boundary of the cell. Failure to account for this boundary effect in the analysis of the interaction of the defect with an applied stress leads to results that are simulation cell-size dependent making the *quantitative* determination of mechanical parameters such as the line tension and the Peierls stress of the dislocation difficult. Indeed, Basinski, Duesbery and Taylor (1971) observed such effects in their study of the interaction of screw dislocations with an applied stress in a sodium lattice. Although the importance of the boundary stress has been realised, a systematic analysis of its effects has been wanting.

In this paper we develop a method that explicitly accounts for the boundary force using linear elasticity, for the case of screw dislocations. It is shown that the boundary force scales as the inverse square of the size of the simulation cell. This formulation is used in conjunction with atomistic simulations to obtain the lattice resistance function for screw dislocations in several close packed metals. In addition, the bow out of a pinned screw dislocation under the influence of an applied stress is studied using a variational principle that incorporates the boundary force, demonstrating that in this case the synthesis of atomistic and continuum methods yields a consistent description of bow out. One outcome of this calculation is that the line tension of the dislocation can be computed directly from atomistics. In the following section we present the derivation of the boundary force after discussing its origin and significance. Section 3 contains the results of the lattice resistance calculations, while the atomistic study of dislocation bow out may be found in Section 4. We conclude with a discussion of the significance of our findings.

2 Simulation methodology and the boundary force

Our objective is the simulation of the interaction of an infinite straight screw dislocation, in an infinite crystal, with an applied stress. To model this problem using a finite simulation cell we choose a cylindrical cell of atoms with axis along the x_2 -direction (cf. fig. 1). The x_1x_2 plane is the slip plane, the x_2 -direction is the line direction as well as the Burgers vector direction of the dislocation. A screw dislocation is placed at the center of this cell at O by displacing

the atoms from their perfect lattice sites according to the continuum linear elastic solution for a Volterra dislocation and this configuration is used as the trial solution for the atomistic energy minimisation. The minimisation is performed keeping the atoms in region F fixed at the positions given by the linear elastic solution; only the atoms in region M (*dynamic region*, a cylinder of radius R) enclosed by F are allowed to move. The relaxed core of the dislocation is thus obtained. The interaction of the dislocation with a homogeneous applied shear stress is simulated by displacing the atoms in both F and M by the displacement fields corresponding to the homogeneous strain that is equivalent to the stress of interest. Again, the atomistic energy minimisation step is performed keeping the atoms in the region F fixed and allowing the atoms in the region M to move. On performing the above procedure, the dislocation moves through the crystal to a new position P , which is determined by the equilibrium condition

$$\tau_{app} + \tau_b(d) + \tau_L(d) = 0, \quad (1)$$

where $d = \overline{OP}$ as shown in fig. 1, τ_{app} is the resolved shear stress which effects a Peach-Koehler force $\tau_{app}b$ in the x_1 -direction (b is the magnitude of the Burgers vector), τ_L is the *lattice resistance function* (Kocks, Argon and Ashby 1975) which is periodic in d and τ_b is the *boundary stress* which is a monotonically increasing (in magnitude) function of d .

We now explore the origin and significance of the boundary stress term. Upon application of a homogeneous strain, the net displacement of the atoms before relaxation in region F and on the external boundary ∂M_e of M is equal to the sum of the elastic displacements due to the dislocation at O ($\mathbf{u}_O$) and the displacements due to the homogeneous strain as dictated by linear elasticity. After relaxation, the dislocation moves to point P ; if the dislocation was set in an infinite crystal, the displacements of the atoms in region F would have been equal to the sum of the elastic displacements due to the presence of the dislocation at P ($\mathbf{u}_P$) and the displacements due to the homogeneous strain. Since the atoms in the region F are held fixed during the relaxation, the boundary condition *after relaxation* is not consistent with the fields of the dislocation at P . This inconsistency causes a spurious increase in the total energy stored in the system, i.e., there is an additional energy cost in moving the dislocation from O to P . This additional energy produces an energetic stress on the dislocation (in the sense of Eshelby 1951)

which we call the *boundary stress*. This boundary stress depends on the radius R of the dynamic region, making the quantities calculated from the results of the simulations, cell-size dependent. The boundary stress is particularly important in the simulations of dislocations in crystals with low lattice resistance such as those with the fcc and hcp structures. In materials with high lattice resistance such as bcc metals this term may be neglected as the lattice resistance term will be several orders of magnitude larger than the boundary term.

In order to derive the boundary stress, we assume that the total energy $\mathcal{E}$ is built up of an elastic energy E and a misfit energy $\mathcal{M}$, i.e., $\mathcal{E} = E + \mathcal{M}$. The misfit energy accounts for the energy required to maintain the slip distribution due to the presence of the dislocation, and the elastic energy is due to the elastic straining of the crystal and may be thought of as arising from a continuous distribution of infinitesimal dislocations. Thus the net change in the energy ($\Delta\mathcal{E}$) on moving the dislocation to the point P is then given by $\Delta E(d) + \Delta\mathcal{M}(d)$. In the absence of the inconsistent boundary condition, the change in elastic energy would vanish (in accordance with a Peierls-Nabarro type model which states that the elastic energy remains unchanged as the dislocation moves through the crystal). We assume that the presence of the inconsistent boundary does not effect the misfit energy, and thus the additional energy due to the inconsistent boundary is entirely elastic. In addition, we assume that the change in elastic energy ΔE computed using a *Volterra model* of the dislocation gives a good approximation to this energy change. These assumptions are valid when the size of the simulation cell (R) is large compared to the core width of the dislocation. Under these assumptions, the change in elastic energy ΔE may be computed and the boundary stress is given by

$$\tau_b(d) = -\frac{1}{b} \frac{\partial \Delta E}{\partial d}, \quad (2)$$

and the lattice resistance function τ_L may be obtained as

$$\tau_L(d) = -\frac{1}{b} \frac{\partial \Delta \mathcal{M}}{\partial d}. \quad (3)$$

In the following discussion, the external boundary of the dynamic region is denoted by ∂M_e , the slip surface $\overline{AO}$ is denoted by ∂M_s and $\partial M_{s'}$ denotes the slip surface $\overline{AP}$ that corresponds to the dislocation at P . All the linear elastic fields associated with the presence of the dislocation at

O are denoted by a subscript O (e.g. $\mathbf{u}_O$) while a subscript P is used to denote fields associated with the dislocation at P . In both cases, the fields correspond to an unconstrained dislocation in an infinite crystal. The dislocation is displaced from O to P , while keeping the displacements on ∂M_e fixed at $\mathbf{u}_O$ (a *constrained* motion of the dislocation). This corresponds to the process that occurs in the atomistic simulation when the dislocation moves under the influence of the applied stress. It is clear that ΔE is the difference in the elastic energy E_2 of the system when the dislocation is at P after the constrained motion and the elastic energy E_1 when the dislocation is at O . The energy E_1 is evaluated as

$$E_1 = \frac{1}{2} \int_{\partial M_s} \mathbf{t}_O \cdot \llbracket \mathbf{u}_O \rrbracket dS + \frac{1}{2} \int_{\partial M_e} \mathbf{t}_O \cdot \mathbf{u}_O dS, \quad (4)$$

where $\mathbf{t}_O$ is the traction vector on the relevant boundary due to the stress field of the dislocation at O ($\mathbf{t}_O = \boldsymbol{\sigma}_O \cdot \mathbf{n}$ where $\boldsymbol{\sigma}_O$ is the stress tensor and $\mathbf{n}$ is the normal to the boundary/surface), and $\llbracket \cdot \rrbracket$ represents the jump in the displacement across the slip surface (i.e., the Burgers vector). The total energy E_2 of the configuration with the dislocation at P (after the constrained motion) may be evaluated as follows. This configuration is taken as the superposition of the fields $\mathbf{u}_P$ due to the presence of the dislocation at P as though in an infinite crystal, and $\Delta \mathbf{u}$ which is an equilibrium displacement field with

$$\Delta \mathbf{u} = \mathbf{u}_O - \mathbf{u}_P, \quad \forall \mathbf{x} \in \partial M_e \quad (5)$$

and with the condition that $\llbracket \Delta \mathbf{u} \rrbracket = \mathbf{0}$ on $\partial M_{s'}$. It must be noted that $\Delta \mathbf{u}$ at a point in the *interior* of M is *not* equal to $\mathbf{u}_O - \mathbf{u}_P$. The energy in the displaced configuration is

$$E_2 = \frac{1}{2} \int_{\partial M_{s'}} \mathbf{t}_P \cdot \llbracket \mathbf{u}_P \rrbracket dS + \frac{1}{2} \int_{\partial M_e} \mathbf{t}_P \cdot \mathbf{u}_P dS + \int_{\partial M_e} \mathbf{t}_P \cdot \Delta \mathbf{u} dS + \frac{1}{2} \int_{\partial M_e} \Delta \mathbf{t} \cdot \Delta \mathbf{u} dS, \quad (6)$$

where $\mathbf{t}_P$ is the traction associated with the stress field of the dislocation at P (as though in an infinite body), $\Delta \mathbf{t}$ is the traction associated with the fields $\Delta \mathbf{u}$. The additional energy ΔE stored in the system due to the boundary condition on ∂M_e may be expressed as

$$\Delta E = E_2 - E_1 = \Delta E^a + \Delta E^b + \Delta E^c, \quad (7)$$

with the three terms being given by

$$\Delta E^a = \frac{1}{2} \int_{\partial M_{s'}} \mathbf{t}_P \cdot \llbracket \mathbf{u}_P \rrbracket dS - \frac{1}{2} \int_{\partial M_s} \mathbf{t}_O \cdot \llbracket \mathbf{u}_O \rrbracket dS, \quad (8)$$

$$\Delta E^b = \int_{\partial M_e} \mathbf{t}_P \cdot (\mathbf{u}_O - \frac{1}{2}\mathbf{u}_P) dS - \frac{1}{2} \int_{\partial M_e} \mathbf{t}_O \cdot \mathbf{u}_O dS, \quad (9)$$

$$\Delta E^c = \frac{1}{2} \int_{\partial M_e} \Delta \mathbf{t} \cdot \Delta \mathbf{u} dS. \quad (10)$$

We choose to partition the energy change in this fashion for convenience as it will be shown below how these three contributions may each be evaluated separately.

In preparation for evaluating the energy difference, we record the isotropic, linear elastic displacement and stress fields for a Volterra screw dislocation (Hirth and Lothe 1968) at a point Q with coordinates $(x_Q, 0)$

$$(u_2)_Q(x_1, x_3) = u_Q(x_1, x_3) = -\frac{b}{2\pi} \arctan\left(\frac{x_3}{x_1 - x_Q}\right). \quad (11)$$

The point Q is a generic point on the slip plane; Q may, for example, be taken to be O or P . The components of the stress tensor $\boldsymbol{\sigma}_Q$ are given by

$$(\sigma_{12})_Q(x_1, x_3) = \frac{\mu b}{2\pi} \left(\frac{\sin \phi}{r'} \right), \quad (\sigma_{32})_Q(x_1, x_3) = -\frac{\mu b}{2\pi} \left(\frac{\cos \phi}{r'} \right) \quad (12)$$

where $\phi = \arctan(x_3/(x_1 - x_Q))$, $r' = \sqrt{(x_1 - x_Q)^2 + x_3^2}$ and μ is the shear modulus. All other displacement and stress components not symmetric to those given above vanish. In the developments that follow, we freely switch between cartesian (x_1, x_3) and polar coordinates (r, ψ) . The notation is simplified by adopting the convention that

$$\sigma_Q = \mathbf{t}_Q \cdot \mathbf{e}_2 = (\boldsymbol{\sigma}_Q \cdot \mathbf{n}) \cdot \mathbf{e}_2 = (\sigma_{12})_Q n_1 + (\sigma_{32})_Q n_3, \quad (13)$$

where $\mathbf{n}$ is the normal to the pertinent boundary and $\mathbf{e}_i$ denotes the basis vector along the i^{th} coordinate axis.

First we compute ΔE^a which requires the evaluation of surface integrals over the domains ∂M_s and $\partial M_{s'}$ for which $\mathbf{n} = \mathbf{e}_3$. Taking r_o to be the elastic core cut-off radius, we see that

$$\frac{1}{2} \int_{\partial M_{s'}} \mathbf{t}_P \cdot \llbracket \mathbf{u}_P \rrbracket dS = \frac{\mu b^2}{4\pi} \ln \frac{R+d}{r_o}, \quad \text{and} \quad \frac{1}{2} \int_{\partial M_s} \mathbf{t}_O \cdot \llbracket \mathbf{u}_O \rrbracket dS = \frac{\mu b^2}{4\pi} \ln \frac{R}{r_o}.$$

It is now immediate that the contribution of these terms to the energy difference is

$$\Delta E^a = \frac{\mu b^2}{4\pi} \ln(1+a), \quad (14)$$

with $a = d/R$.

To evaluate ΔE^b we note that the unit normal to the external boundary ∂M_e is given by $\mathbf{n}(\psi) = \cos \psi \mathbf{e}_1 + \sin \psi \mathbf{e}_3$. Using eqs. 12 and 13 it follows that $\mathbf{t}_O \cdot \mathbf{e}_2 = \sigma_O = 0$ on ∂M_e and hence from eq. (9)

$$\Delta E^b = \int_{\partial M_e} \mathbf{t}_P \cdot (\mathbf{u}_O - \frac{1}{2} \mathbf{u}_P) dS = \int_{\partial M_e} \sigma_P (u_O - \frac{1}{2} u_P) dS. \quad (15)$$

Since in this case $x_P = d$, one obtains that

$$\sigma_P(R, \psi) = \frac{\mu b d \sin \psi}{2\pi r'^2}. \quad (16)$$

for points with coordinates (R, ψ) on ∂M_e noting that $\phi = \arctan(\sin \psi / (\cos \psi - a))$ and $r' = \sqrt{R^2 + d^2 - 2Rd \cos \psi}$. Substituting all relevant quantities into eq. (15), results in

$$\Delta E^b = -\frac{\mu b^2}{4\pi^2} a I_1(a) \quad (17)$$

where

$$I_1(a) = \int_{-\pi}^{\pi} \left[\left(\psi - \frac{1}{2} \arctan \left(\frac{\sin \psi}{\cos \psi - a} \right) \right) \frac{\sin \psi}{\rho'^2} \right] d\psi, \quad (18)$$

and $\rho'^2 = (1 + a^2 - 2a \cos \psi)$.

We now turn to the evaluation of ΔE^c . From eq. (10) we have that

$$\Delta E^c = \frac{1}{2} \int_{\partial M_e} \Delta \mathbf{t} \cdot \Delta \mathbf{u} dS = \frac{1}{2} \int_{\partial M_e} \Delta \sigma \Delta u dS \quad (19)$$

with $\Delta \mathbf{u} = \Delta u \mathbf{e}_2$ and $(\Delta \boldsymbol{\sigma} \cdot \mathbf{n}) \cdot \mathbf{n} = \Delta \sigma$. The evaluation of ΔE^c , requires both knowledge of Δu on ∂M_e , which is provided by boundary conditions, and of $\Delta \sigma$. Since Δu is an equilibrium field, it satisfies the elastic equilibrium equation (Navier's equation) in M ,

$$\nabla^2(\Delta u) = 0 \quad (20)$$

with the associated boundary condition that on ∂M_e

$$\Delta u = -\frac{b}{2\pi} \left(\arctan \left(\frac{x_3}{x_1} \right) - \arctan \left(\frac{x_3}{x_1 - d} \right) \right). \quad (21)$$

This Dirichlet problem for Δu in the interior of M may be solved using the Poisson integral formula (John 1982), i.e.,

$$\Delta u(r, \psi) = -\frac{b}{4\pi^2} \int_{-\pi}^{\pi} \left[\left(\theta - \arctan \left(\frac{\sin \theta}{\cos \theta - a} \right) \right) \left(\frac{R^2 - r^2}{R^2 + r^2 - 2rR \cos(\psi - \theta)} \right) \right] d\theta \quad (22)$$

where (r, ψ) are the polar coordinates of an interior point of M . To evaluate $\Delta\sigma$ on ∂M_e we evaluate the strain field corresponding to the displacement field given by eq. (22) and use the elastic constitutive equations. This results in

$$\Delta\sigma = \frac{\mu b}{2\pi^2 R} J(\psi) \quad (23)$$

with $J(\psi)$ defined by

$$\begin{aligned} J(\psi) &= \lim_{\rho \rightarrow 1} \frac{2\pi^2}{b} \frac{\partial \Delta u(\rho, \psi)}{\partial \rho} \\ &= \lim_{\rho \rightarrow 1} \int_{-\pi}^{\pi} \left[\left(\theta - \arctan \left(\frac{\sin \theta}{\cos \theta - a} \right) \right) \left(\frac{2\rho - (\rho^2 + 1) \cos(\psi - \theta)}{(1 + \rho^2 - 2\rho \cos(\psi - \theta))^2} \right) \right] d\theta, \end{aligned} \quad (24)$$

where ρ is the normalised value of r , i.e., $\rho = r/R$. Substituting eqs. 21 and 23 into eq. (19) we find

$$\Delta E^c = -\frac{\mu b^2}{8\pi^3} I_2(a), \quad (25)$$

with

$$I_2(a) = \int_{-\pi}^{\pi} J(\psi) \left(\psi - \arctan \left(\frac{\sin \psi}{\cos \psi - a} \right) \right) d\psi. \quad (26)$$

Having evaluated the various terms that contribute to the elastic energy as a result of the inconsistent boundary condition, we are now in a position to evaluate the boundary stress. Collecting terms ΔE^a , ΔE^b and ΔE^c from eqs. 14, 17 and 25 one obtains that

$$\Delta E = \frac{\mu b^2}{4\pi^2} Z(a) \quad (27)$$

where $Z(a)$ is given by

$$Z(a) = \pi \ln(1 + a) - a I_1(a) - \frac{1}{2\pi} I_2(a). \quad (28)$$

It is remarkable that ΔE does not depend explicitly on d and R , but depends only on their ratio a . Also, the result is independent of the elastic core cutoff radius r_o (on the assumption that it remains fixed).

Although the above discussion was restricted to isotropic linear elastic solids, our method may be applied to the anisotropic case as well. We indicate the changes that are required to

accomplish this in the case of hcp crystals with $\langle 11\bar{2}0 \rangle$ type screw dislocations. In this case the simulation cell is chosen to be an elliptic cylinder, i.e., the boundary ∂M_e satisfies the equation

$$x_1^2 + \frac{x_3^2}{k^2} = R^2, \quad (29)$$

where $k = \sqrt{C_{44}/C_{66}}$ and C_{ij} have their usual meanings (Hirth and Lothe 1968). The terms ΔE^a and ΔE^b can be evaluated straightforwardly by following the steps of the previous section. To evaluate ΔE^c we note that Δu satisfies

$$\frac{\partial^2 \Delta u}{\partial x_1^2} + k^2 \frac{\partial^2 \Delta u}{\partial x_3^2} = 0 \quad (30)$$

with boundary conditions as in eqs. 5. This equation may be solved after a coordinate transformation $(x_1, x_3) \rightarrow (y_1, y_3)$ where $y_1 = x_1$ and $y_3 = x_3/k$; Δu is harmonic in the new coordinates and ∂M_e transforms to a circle of radius R , and thus Δu may be calculated using the Poisson integral formula. The traction $\Delta \sigma$ is calculated using the elastic constitutive equations and ΔE^c is evaluated as before. The final expression for ΔE may be written in this case as

$$\Delta E = \frac{C_{44}b^2}{4\pi^2} Z(a, k) \quad (31)$$

where in this case the dimensionless energy change Z depends on both a and the ratio k which is a measure of the elastic anisotropy. The case of isotropic solids is obtained from eq. (31) by using $k = 1.0$ and $C_{44} = \mu$.

The boundary stress may now be obtained using eq. (2) as

$$\tau_b(a) = -\frac{C_{44}b}{4\pi^2 R} \frac{\partial Z(a, k)}{\partial a} = -\frac{C_{44}b}{4\pi^2 R} F(a, k), \quad (32)$$

where $F(a, k)$ is the derivative of Z with respect to a . The dimensionless stress F is plotted in fig. 2. For small values of a , Z admits a quadratic approximation of the form

$$Z(a, k) = \frac{1}{2} A(k) a^2, \quad (33)$$

which demonstrates that when $a \ll 1$ (i.e., $d \ll R$) the boundary stress is linear in the dimensionless parameter a . This linear nature of F in the indicated regime is evident from fig. 2. The constant A , which depends on the value of k , is the *boundary stress coefficient* and the boundary

stress τ_b becomes

$$\tau_b(d) = -\frac{C_{44}bA(k)}{4\pi^2 R^2}d \quad (34)$$

The values of the boundary stress coefficient are computed to be 6.28 for the isotropic case and 6.19 for the case of titanium (HCP). It is clear from eq. (34) that the boundary force is directly proportional to d for a given R and for a given d depends on the inverse square of the size of the simulation region M . Assuming that a typical Burgers vector is of the order of $5.0\text{\AA}$ and that the radius of the simulation cell is about $50.0\text{\AA}$ one obtains a boundary stress of about 0.00025μ , when d is taken to be one Burgers vector. Thus the boundary effects become highly significant in the cases of materials with low lattice resistance (fcc and hcp metals). On the other hand, in the case of BCC screw dislocations, the boundary term may be neglected in comparison with the Peierls stress which is two orders of magnitude larger.

In light of our development of the boundary stress, we now proceed to derive the equilibrium condition (eq. (1)). We assume that the dislocation has moved to the point P under the influence of the applied stress τ_{app} and is in equilibrium. The principle of virtual work states that if the dislocation is given an arbitrary virtual displacement δ from P , the net external work done will equal the change in the net energy stored (per unit thickness along the x_2 -direction), i.e.,

$$\underbrace{\tau_{app}b\delta}_{\text{external work}} = \underbrace{\frac{\partial\Delta E}{\partial d}\delta + \frac{\partial\Delta\mathcal{M}}{\partial d}\delta}_{\text{change in energy}}. \quad (35)$$

Eq. 35 can be rewritten as

$$(\tau_{app} + \tau_b(d) + \tau_L(d))\delta = 0. \quad (36)$$

Making use of eqs. 2 and 3, and noting that δ is arbitrary, the equilibrium condition (eq. (1)) is obtained. By virtue of the continuum arguments outlined here, we are now in a position to use the boundary force in the context of explicit atomistic simulation.

It may be noted that, in the isotropic case, the boundary force can be derived by placing an image dislocation at a point $(R^2/d, 0)$ on the x_1 axis. The resulting fields obtained by superposition will then satisfy the condition eq. (5) and the boundary force is now equal to the force exerted by the image dislocation on the dislocation at P . The advantage in using the energetic method

of obtaining the boundary force is the generalization to the anisotropic case, and possibly for other defects such as the edge dislocation.

3 Lattice resistance functions and Peierls stress

In this section we present the results of the calculation of the lattice resistance function for screw dislocations in several close packed metals. As mentioned above, the form of the lattice resistance function was discussed by Kocks, Argon and Ashby (1975). Although atomistic calculations have been used previously to compute the Peierls stress which corresponds to a single point on the lattice resistance curve, it is one of the aims of the present work to compute the entire lattice resistance function from atomistic simulation. This is achieved using the following method. The position of the dislocation (d) is monitored as a function of the applied stress. The applied stress is sufficiently small so that the displacement d is small compared with R ; thus the linear boundary stress approximation may be applied (eq. (34)). From the equilibrium condition (eq. (1)) the lattice resistance function can be obtained as

$$\tau_L(d) = -(\tau_{app} + \tau_b(d)). \quad (37)$$

The motion of the dislocation is monitored relative to an initial equilibrium position labeled as point O which is chosen to correspond to a Peierls valley. To obtain the position d of the dislocation the following procedure is adopted. The slip distribution on the slip plane (x_1x_2) i.e., distribution of $\llbracket u_2 \rrbracket$ as a function of x_1 is obtained using the method given by Miller and Phillips (1996). The position d of the dislocation is taken to be that value of x_1 at which $\llbracket u_2 \rrbracket$ equals one half the Burgers vector ($b/2$). For this procedure to be meaningful it is essential that as the dislocation moves through the crystal, the slip distribution moves in an essentially self similar fashion, which we find is a good approximation in the cases considered here.

To obtain the relationship between the applied stress τ_{app} and d , the stress is applied in small increments and the configuration is relaxed at every step as explained before. Once the applied stress reaches a desired maximum value (this is chosen so that the resulting d/R value is not overly large), the stress is decremented until it reaches zero, i.e., the direction of loading is reversed. Fig. 3 shows the net resistance that the dislocation would have to overcome in its

journey through the crystal (i.e., $\tau_b + \tau_L$). The expected τ_{app} vs. d curve is $OABCDEFGH$ as shown in fig. 3 in the loading branch and $GHIJKLMO$ during the unloading process. Thus if the applied stress is sufficiently large, the dislocation travels through various Peierls wells (for example OA and BC are in different Peierls wells, as are IJ and KL in the unloading branch). It is clear that the τ_{app} vs. d curve obtained will depend on the simulation cell size. On the other hand, if the boundary term is subtracted off using eq. (37), the results should be found to be cell size independent. Also the lattice resistance function computed from various Peierls wells must agree (since the lattice resistance is periodic), in addition to being simulation cell size independent.

To examine the validity of our ideas concerning the boundary force, we have examined the response of screw dislocations to an applied stress in aluminum and titanium. The point of these calculations is to revisit the idea of lattice resistance of dislocations from an atomistic perspective while approximately accounting for the finite simulation cell size.

Our first test case was the simulation of a $\frac{a}{2}\langle 110 \rangle$ type screw dislocation in fcc aluminum which was performed using the embedded atom potentials developed by Ercolessi and Adams (1993). For details on the embedded atom method, see Daw and Baskes (1984). Fig. 4 shows the relationship between τ_{app} and d (compare with fig. 3). It is clear that this curve is simulation cell-size dependent. The lattice resistance function computed using eq. (37) is given in fig. 5. In these calculations the value of the boundary force coefficient was taken to be 6.3. It is seen that the computed lattice resistance function is simulation cell-size independent, with a resulting Peierls stress of 0.00068μ .

Our additional test was made on hcp titanium. In this case, embedded atom potentials developed by Igarashi, Khantha and Vitek (1991) were used. The screw dislocations simulated had a Burgers vector of $\frac{a}{3}\langle 11\bar{2}0 \rangle$ on the basal plane. The lattice resistance function is plotted in fig. 6. The anisotropy ratio k for Titanium is 1.06 and the boundary force coefficient A for this value of k is 6.2. This value for A was found to be too high; and when A was set to 5.5 the lattice resistance obtained from different Peierls wells turned out to be consistent. The value of the Peierls stress is about 0.00034μ .

It must be noted that in plotting the lattice resistance functions in figs. 5 and 6 using eq. (37),

the negative sign appearing in the equation has been dropped. Thus the resistance function must be interpreted as the external stress necessary to overcome the lattice resistance. In both the cases discussed above, the lattice resistance functions from different Peierls wells are plotted in the same graph. It is thus evident that the computed lattice resistance functions are periodic. It is interesting to note that in all the cases, the lattice resistance functions are multi-welled. The screw dislocations in all the materials discussed above undergo a splitting reaction into Shockley partials and thus the lattice resistance curves are for these extended dislocations. The effect of this splitting on the boundary force is discussed in Appendix 1. The value of A based on isotropic elasticity works well for the case of Al while in the case of Ti the value of A had to be set to 5.5 (as opposed to 6.2 given by the analytic calculation) to obtain consistent values from different Peierls wells (i.e., for the resistance function to be periodic).

4 Bow out of a pinned dislocation segment

The simulation of the bow out of a pinned dislocation segment is an important step towards understanding the mechanics of Frank-Read sources. Work in this direction has hitherto been restricted to continuum formulations. Foreman (1967) applied Brown’s self-stress (Brown 1964) approach to simulate dislocation bow out. Assuming that the dislocation behaves like a flexible string with a line tension T , a simpler theory is obtained (Nabarro 1967, de Wit and Koehler 1959). The latter theory has the advantage of simplicity and we adopt it for the interpretation of the results of the atomistic simulations. The goals of these simulation are i) to examine the validity of the concept of line tension from an atomistic viewpoint and to compute its value from “first principles” and ii) to compare the shape of the dislocation bow out predicted by the continuum theory with that obtained from atomistics.

The atomistic simulation of bow out of a pinned segment under an applied stress is achieved as follows. A straight screw dislocation is placed along the axis of a cylindrical cell of atoms of length L (the axis of the cylinder is the x_2 -axis in fig. 1), with the radius of the dynamic region M set to R . A strain corresponding to the applied stress τ_{app} is imposed on this configuration and the energy is minimised with respect to the atomic coordinates in the dynamic region. In

the energy minimisation step, in addition to the atoms in region F , the atoms on the $x_2 = 0$ and $x_2 = L$ planes are held fixed imitating the pinning effect on the dislocation.

To obtain the equilibrium shape of the bow out as predicted by continuum theory, we consider a screw dislocation on the x_2 axis pinned at $x_2 = 0$ and $x_2 = L$, i.e., the length of the pinned segment is L . Let the equilibrium shape of the dislocation be given by the function $x_1 = f(x_2)$ (cf. fig. 7). The equilibrium shape is given by the function that minimises the functional

$$I(f) = \int_0^L \left(T\sqrt{1+f'^2} - \tau_{app}bf + \frac{\lambda}{2}f^2 \right) dx_2, \quad (38)$$

f' is the derivative of f with respect to x_2 and $\lambda = A\mu b^2/(4\pi^2 R^2)$, where A is the boundary force coefficient. The quadratic term accounts for the additional energy due to the fixed boundary and is absent from a standard continuum formulation. It is assumed in this formulation that the applied stress is larger than the Peierls stress so that the lattice resistance (misfit energy) can be neglected. In addition, the applied stress τ_{app} is also assumed to be small compared to the shear modulus μ of the material. The function f satisfies the Euler-Lagrange equation of the variational principle eq. (38), i.e.,

$$\frac{d}{dx_2} \left(\frac{f'}{\sqrt{1+f'^2}} \right) + \left(\frac{\tau_{app}b}{T} - \frac{\lambda}{T}f \right) = 0, \quad f(0) = f(L) = 0, \quad (39)$$

the solution of which is (assuming $|f'| \ll 1$ since $\tau_{app} \ll \mu$)

$$f(x_2) = \frac{\tau_{app}b}{\lambda} \left(1 - \frac{\sinh \sqrt{\frac{\lambda}{T}}(L-x_2) + \sinh \sqrt{\frac{\lambda}{T}}x_2}{\sinh \sqrt{\frac{\lambda}{T}}L} \right) \quad (40)$$

which expresses the fact that under the influence of the boundary stress the shape of the bow out is given by a catenary. Noting that the maximum bow out d occurs at $x = L/2$, we find that

$$d = f(L/2) = \frac{\tau_{app}b}{\lambda} \left[1 - \operatorname{sech} \left(\frac{L}{2} \sqrt{\frac{\lambda}{T}} \right) \right]. \quad (41)$$

The following strategy is adopted in computing the line tension for the results of the atomistic simulations. The maximum bow out d is “measured” from the results of an atomistic simulation. If d is known, the line-tension T can be obtained from eq. (41) as

$$T = \frac{\lambda L^2}{4 \left(\operatorname{sech}^{-1} \left[\left(1 - \frac{\lambda d}{\tau_{app}b} \right) \right] \right)^2}. \quad (42)$$

If the effect of the boundary is not explicitly accounted for ($A \rightarrow 0$), then d is related to T using

$$d = \lim_{\lambda \rightarrow 0} \frac{\tau_{app} b}{\lambda} \left[1 - \operatorname{sech} \left(\frac{L}{2} \sqrt{\frac{\lambda}{T}} \right) \right] = \frac{\tau_{app} b L^2}{8T} \quad (43)$$

and one may obtain an *uncorrected* estimate of the line tension as

$$T_u = \frac{\tau_{app} b L^2}{8d}. \quad (44)$$

These results were used to perform atomistic simulations of dislocation bow out for $\frac{a}{2}\langle 110 \rangle$ type screw dislocation in Al using the EAM potentials developed by Ercolessi and Adams (1993). The values of the line tension computed for various lengths of the dislocation at various levels of applied stresses are tabulated in tables 1, 2 and 3 (in all these cases the value of R is 40.0Å). The values of line tension computed using eq. (42), which incorporate the boundary stress, are length independent. Also, the values do not depend strongly on the values of the applied stress. Table 4 shows the computed value of the line tension using a larger simulation cell ($R = 57.0\text{\AA}$). It is seen that the computed values agree well with those computed using the smaller cell. In addition, it is seen that the values of line tension computed from eq. (42) and those computed from eq. (44) agree when the cell size becomes larger and when the length of the dislocation is made smaller, as is evident from tables 1 and 4. At larger lengths of the dislocation the bow out d becomes larger (for a given value of τ_{app}) and the quadratic approximation eq. (33) for the additional energy is an underestimate and hence the boundary force is underestimated. Consequently, the line tension is overestimated, as seen in table 3. A second interesting trend is seen in the estimates for the line tension in the case where the boundary contribution is *not* accounted for. Here as the dislocation length increases, so too does the apparent line tension. This effect may be attributed to the boundary force which mimics the effects of a higher line tension preventing the development of a full bow out.

It is also useful to compare the shape of the bow out as predicted by the continuum formulation (eq. (40)) and that obtained from atomistics. It is seen that the shape predicted by the continuum theory which accounts for the boundary force is in close agreement with that obtained from atomistics (cf. fig. 8). Thus the continuum formulation (eq. (38)) provides a satisfactory model for the study of dislocation bow out. In addition the concept of line tension is found to be

meaningful from an atomistic perspective allowing for a determination of the line tension from “first principles”. The value of line tension is found to be about $0.42\mu b^2$ which is close to the conventional approximation of $0.5\mu b^2$ (Nabarro 1967). It must be noted that this dislocation undergoes a splitting reaction into Shockley partials as described before and thus the computed line tension is for the extended dislocation. It is noted that even with the boundary force correction, the computed values of the line tension are slightly different for various levels of applied stress. This is believed to arise from the neglect of the lattice resistance term.

Fig. 9 shows a plot of $\llbracket u_2 \rrbracket$ as a function of the position on the slip plane extracted from the results of an atomistic calculation using the technique given in Miller and Phillips (1996). The value of d is found by sectioning this surface at a value of one half of the Burgers vector. The positions of atoms on the atomic planes that sandwich the slip plane is are plotted in fig. 10. A careful study of this figure brings out the discrete nature of the dislocation bow out and the core structure of a curved dislocation.

5 Conclusion

In this paper, we have described a method for accounting for the additional boundary stresses that act on a dislocation due to the use of a finite sized cell in an atomistic simulation. An explicit formula for the boundary stress is derived for the case of the screw dislocation. The formula was derived based on the Peierls-Nabarro model and a linear elastic reckoning of the elastic energy due to an inconsistent boundary. The boundary stress is proportional to the inverse square of the size of the simulation cell. This formulation was then used to obtain the lattice resistance function for screw dislocations in several close packed metals. In addition, a simple 3D configuration for the bow out of a screw dislocation was also studied and the line tension of the dislocation was computed for the case of aluminum.

The explicit accounting of the boundary stress is essential to obtain meaningful *quantitative* values from the results of an atomistic simulation. This is evident from the simulation of the dislocation bow out that is presented here. The effects of the far-field boundary conditions may be overcome with the use of large simulation cells when empirical or semi-empirical potentials are

used in the simulation, however it proves to be a serious difficulty in calculations using density functional theory. Thus this method might be especially useful in those simulations where there are severe restrictions on the size of the simulation cell.

Appendix : Effect of dislocation splitting on the boundary force

It was noted in section 3 that the screw dislocations in aluminum and titanium undergo a splitting reaction. Here we compute the boundary force when the dislocation is split assuming a splitting distance of $2s$ ($s = 4.0\text{\AA}$ for aluminum and $s = 6.1\text{\AA}$ for titanium). It is also assumed that this distance does not change as the dislocation moves under the influence of the applied stress - a premise that appears to be in good agreement with observations. Under these assumptions one can compute the boundary stress to be

$$\tau_b(d) = -\frac{C_{44}bA(k, c)}{4\pi^2 R^2}d \quad (45)$$

for $d \ll R$, where $c = s/R$. This relation can be derived using equations eqs. 8, 9 and 10 where $\mathbf{u}_P$ is taken to be the sum of the displacement fields due to two screw dislocations with Burgers vector $b/2$ located at $x_1 = d - s$ and $x_1 = d + s$. In the derivation the edge part of the Burgers vector of the Shockley partials is neglected, and thus eq. (45) is approximate. It is seen that the boundary stress coefficient depends on the splitting ratio c in addition to the anisotropy ratio k . A plot of the boundary force coefficient as a function of the splitting ratio is given in fig. 11. The value of A is seen to be unaffected when the splitting is small ($c < 0.1$). This condition is satisfied in the cases considered here and the effect of splitting is thus small.

Acknowledgements

We are grateful to V. Bulatov, A. Carlsson, R. Clifton, M. Fivel and M. Khantha for their valuable comments. Thanks are also due to R. Miller and E. Tadmor for many useful discussions. Support for this work by NSF under Grant No. CMS-9414648 is gratefully acknowledged. We thank the referee for suggesting the image dislocation argument to arrive at the result for the boundary stress.
